Abstract—Most current wireless IEEE 802.11 networks rely on a power-threshold based carrier-sensing multi-access (CSMA) mechanism to prevent packet collisions, in which a transmitter permits its transmission only if the locally measured aggregate interference power from all existing transmissions is below a pre-specified power-sensing threshold. However, such a mechanism cannot completely guarantee interference-safe transmissions, leading to the so-called hidden-node problem, which causes degradation in throughput and fairness performance. Traditionally, ensuring interference-safe transmissions was addressed by simple models of conflict graphs, rather than by the realistic signal-to-interference-and-noise ratio (SINR) model. This paper presents the first viable solution for fully interference-safe transmissions that (1) assumes an accurate SINR model, and (2) is compatible with the carrier-sensing mechanism in existing CSMA networks. Specifically, we determine a proper interference-safe power-sensing threshold by considering both the effects of (i) arbitrary ordering of local interference power measurements, and (ii) ACK frames. We compare our interference-safe solution with other solutions, and provide extensive evaluation on its throughput and fairness performance.

Index Terms—Carrier-Sensing Multi-Access, Interference-Safeness, SINR Model, Interference Power Measurement

I. INTRODUCTION

Carrier-sensing multi-access (CSMA) networks (e.g., WiFi), a class of distributed and randomized medium-access protocols, are widely deployed in enterprises and homes. Despite its simplicity of implementation, CSMA is plagued with performance issues. Substantial improvements have been proposed to improve the efficiency of CSMA networks with higher capacity and lower control overhead. However, many previous studies are either 1) based on an over-simplified model that relies on a simple notion of “conflict graphs” and ignores the physical layer characteristic of signal-to-interference-and-noise ratio (SINR) in wireless communications, or 2) not compatible with the distributed carrier-sensing mechanism in today’s CSMA protocol. As a result, the effectiveness of these proposed solutions remains dubious. This paper focuses on an important performance problem in CSMA networks, caused by failure of CSMA protocol to ensure interference-safe transmissions among simultaneously transmitting links (also known as hidden node problem). Previous studies have addressed interference-safe transmissions and hidden node problem are based on “conflict graph” models for the interference and carrier-sensing operations, which are crude approximations to the more realistic physical-layer wireless communication model.

This paper presents a viable solution that (1) uses an accurate SINR model, considering the effects of arbitrary ordering of carrier-sensing operations, and the presence of ACK frames; and (2) is compatible with the existing CSMA networks, relying on only basic power-threshold based carrier-sensing operations. Our results close a vital gap in enhancing the performance of practical CSMA in a realistic setting.

A. Overview of Results

The idea of CSMA is that before a transmitter attempts its transmission, it needs to infer the channel condition. If the transmitter infers that its transmission is not interference-safe, namely possibly upsetting (or be upset by) any on-going transmissions, then it defers its transmission. A common approach in the extant CSMA protocol (which we call Aggregate-interference-Power Carrier-Sensing (APCS)) is to let the transmitter measure the aggregate interference power — the total power of all concurrent transmissions and the background noise at the pending transmitter. A transmission will proceed only if the locally measured aggregate interference power is below a pre-specified power-sensing threshold.

It is vital to set the power-sensing threshold properly. An improperly high threshold fails to safe-guard interference, leading to the hidden node problem [1], whereas an improperly low threshold causes over-conservative protection against interference and inefficiency in throughput, leading to the exposed node problem [1]. The difficulty to determine a proper threshold is due to two salient effects of CSMA:

1) (Effect of Ordering): CSMA is a distributed protocol, such that the transmitters decide their transmissions without global coordination, using APCS before each transmission. However, the transmitters may follow an arbitrary order, and this introduces a unique challenge in guaranteeing interference-safe transmission that has not been studied before. Specifically, an earlier transmitter that measured low interference power before the transmission may be disrupted by a later transmitter that causes unforeseen higher interference power to it. A proper power-sensing threshold should tolerate arbitrary ordering of local measurements of transmitters, by which the local interference power may rise in the future without the on-going transmitter’s awareness. To our best knowledge, all past works on ensuring interference-safe transmission (or removing hidden-nodes) in CSMA networks have ignored this subtle yet important effect.

2) (Effect of ACKs): CSMA in wireless networks is often an ACK-based protocol, in which the receivers are required to reply an ACK frame for each successful transmission. Hence, the power-sensing threshold not only must ensure
the successful receptions of DATA frames in one direction, but also the successful receptions of ACK frames in the opposite direction in the presence of other interfering transmitters. The consideration of bi-directional communications in terms of SINR will complicate the determination of power-sensing threshold.

Furthermore, we provide performance evaluation of CSMA networks with APCS, and show that our result is a viable approach. We also observe that the power-sensing threshold provided by our theoretical study is relatively robust in spite of uncertain parameters from the channel model.

B. Comparison to Related Work

Ensuring interference-safe transmissions has been addressed in the extant literature (e.g., [1]–[4]), in which a CSMA network was modeled by a “conflict graph” that is induced by a geometric graph based on the transmitters and receivers. The conflict graph model relies on the binary constraint among pairs of transmitters, which does not consider the additive property of wireless signals. Hence, it calls for a more realistic model with signal-to-interference-and-noise ratio (SINR). The study of hidden node problem in an SINR model has begun recently. Ref. [5] found that the common CTS/RTS mechanism, which relies on the assumption that the decodable range of a CTS/RTS message is comparable to the interfering range, is not sufficient to ensure interference-safe transmissions in an SINR model, because the sum of individually insignificant interference power can still be considerably large in an SINR model, and hence, a transmitter can affect very far-off nodes, other than those that can decode its packets. Two previous studies akin to this work are our prior work [6], [7]. In [6], we proved the scaling law of capacity of CSMA in an SINR model. But the result relies on a simplified model of power-threshold based carrier-sensing, which ignores the effect of ordering of local measurements. This work extends that study to consider the effect of ordering in CSMA.

Previously, [7] proposed an alternate approach called Incremental-Power Carrier-Sensing (IPCS), which ensures interference-safe transmissions under an SINR model by inferring the distances among transmitters with local measurement of incremental power changes at each node. Specifically, in IPCS, a transmitter will defer transmission if the incremental power change measured recently is above a power threshold. IPCS requires modification to the existing standard CSMA protocol, because the carrier-sensing mechanism of the latter compares the current absolute power measured (not incremental power changes recently) against a threshold. In other words, IPCS is not an off-the-shelf solution to the hidden node problem. In contrast, this work is based on the simpler idea of Aggregate-interference-Power Carrier-Sensing (APCS), which requires no modification to the existing CSMA protocol, because it also compares the absolute power measured against a threshold. We compare the two carrier-sensing approaches by evaluation and analysis. Note that for benchmarking IPCS with standard carrier sensing, [7] also used the same power-sensing threshold optimized for IPCS for standard carrier sensing. However, the power-sensing threshold for IPCS may not be optimal for standard carrier sensing. In this paper, we provide a power-sensing threshold appropriate for standard carrier sensing. Our solution of APCS can be shown to have comparable performance with IPCS.

There are other studies [1], [8] to address a related problem of exposed nodes. We note that there is an inevitable trade-off between hidden node problem and exposed node problem [1], as a solution addressing one of the problems often causes the other problem. Since there is a lack of thorough study for hidden node problem in a realistic setting of SINR model, it is difficult to properly address both problems simultaneously. Our results in this paper solve the former problem and provide a cornerstone for a complete solution for both problems in an SINR model.

II. Motivating Examples

We first illustrate the effects of ACK frames and ordering of local measurements in SINR model, through some motivating examples. Consider Fig. 1 with three transmitter-receiver pairs with the same transmission distance $d$ arranged in parallel.

![Fig. 1. Three transmitter-receiver pairs arranged in parallel.](image)

The signal-to-interference-and-noise ratio (SINR) from node $x$ to node $y$ in the presence of a set of concurrent transmitters $N$ is defined as:

$$\text{SINR}_{x \rightarrow y} = \frac{P_{tx}|x - y|^{-\alpha}}{N_0 + \sum_{z \in N} P_{tx}|z - y|^{-\alpha}}$$

(1)

where $P_{tx}$ is the transmission power, $N_0$ is a background noise and $\alpha$ is the path-loss exponent.

A receiver can successfully receive the data from its transmitter, if the SINR at the receiver is above a certain threshold $\beta$. For instance, if $r_1$ can receive data from $t_1$ in the presence of a set of concurrent transmitters $\{t_2, t_3\}$, it must satisfy:

$$\text{SINR}_{t_1 \rightarrow r_1} = \frac{P_{tx}|t_1 - r_1|^{-\alpha}}{N_0 + P_{tx}|t_2 - r_1|^{-\alpha} + P_{tx}|t_3 - r_1|^{-\alpha}} \geq \beta$$

For simplicity, we let $P_{tx} = 1$, $N_0 = 0$, $\alpha = 2$ and $\beta = 1$.

**Example 1:** (Effect of ACKs) Let $h = l = 1.2d$ in Fig. 1. We obtain the SINRs at the receivers as:

$$\text{SINR}_{t_1 \rightarrow r_1} = \text{SINR}_{t_2 \rightarrow r_2} = \frac{1}{(2.6)\cdot2 + (1.56)\cdot2} = 1.79,$$

$$\text{SINR}_{t_3 \rightarrow r_2} = \frac{1}{(1.56)\cdot2 + (1.56)\cdot2} = 1.22$$

(2)

Since $\beta = 1$, it appears that all receivers can receive the data from their transmitters in spite of interfering transmissions.

However, CSMA protocol also requires the transmission of an ACK frame after the transmission of DATA frame to confirm successful reception. Otherwise, the transmitter will take it as a failed transmission, and re-transmit data later. If $r_2$ begins to transmit ACK to $t_2$, the SINR at $t_2$ becomes:

$$\text{SINR}_{t_2 \rightarrow r_2} = \frac{1}{(1.2)^2 + (1.2)^2} = 0.72$$

(3)
The reverse transmission $r_2 \rightarrow t_2$ is not successful, and hence the transmission $t_2 \rightarrow r_2$ is considered unsuccessful by $t_2$.

In general, we have to consider the interference from all possible transmitters (for DATA frames) and receivers (for ACK frames). For instance, if $t_1$ and $r_3$ are transmitting,

$$\text{SINR}_{t_2 \rightarrow r_2} = \frac{1}{(1.5b)^{-2} + (1.2)^{-2}} = 0.9$$

Hence, $r_2$ is also unable to receive DATA frame from $t_2$ in the presence of interfering $t_1$ and $r_3$.

To prevent collisions, CSMA relies on local interference power measurement. The locally measured interference and noise power from the set of concurrent transmitters $N$ and the background noise obtained at transmitter $x$ before the transmission is denoted by:

$$P_x[N] \triangleq N_0 + \sum_{z \in N} P_{tx}|z - x|^{-\alpha}$$

By Aggregate-interference-Power Carrier-Sensing (APCS), transmitter $x$ proceeds with transmission, only if $P_x[N] \leq t_{cs}$ for a pre-specified power-sensing threshold $t_{cs}$.

In Example 1, transmission $t_2 \leftrightarrow r_2$ is unsuccessful, whenever two other transmissions ($t_1 \leftrightarrow r_1$ and $t_3 \leftrightarrow r_3$) are present. To preclude this from happening, one can set:

$$t_{cs} = \min \left\{ P_{t_1}, P_{t_2}, P_{t_3}, P_{r_1}, P_{r_2}, P_{r_3} \right\} = \frac{1}{(1.5b)^{-2} + (1.2)^{-2}} = 0.9 - \epsilon$$

for some small $\epsilon$. Then, any transmitter among $t_1, t_2, t_3$ is able to infer if other two transmissions are present or not.

But such a setting requires the knowledge of network topology. This poses a question that how we can determine a proper power-sensing threshold in APCS to ensure interference-safe transmissions without the full knowledge of network topology. The setting of power-sensing threshold should require minimum a-priori information and be applicable to universal topologies.

**Example 2: (Effect of Ordering)** We consider the scenario that with a given power-sensing threshold $t_{cs}$, we can rearrange the network topology. In fact, whatever given value of $t_{cs}$ for Fig. 1, there always exist values of $h, l$, such that the local interference power at a transmitter can exceed $t_{cs}$ unawares. For a given $t_{cs}$, we set $h, l$ such that they satisfy:

$$h^{-\alpha} = t_{cs}, \quad l^{-\alpha} + (h + l)^{-\alpha} = t_{cs}$$

We suppose that the transmitters follows the sequence of local measurements as in Fig. 2.

![Fig. 2. A sequence of local interference power measurements.](image)

Initially, there is no transmission. First, $t_1$ measures the interference power as $P_{t_1} = 0 \leq t_{cs}$, and proceeds with transmission. Next, $t_2$ measures the interference power as $P_{t_2} = t_{cs}$, and proceeds with transmission. Lastly, $t_3$ measures the interference power as $P_{t_3} = t_{cs}$, and also proceeds with transmission. However, after $t_3$’s transmission, the interference power at $t_2$ rises to $P_{t_2} = t_{cs}$, which prevents interference-safe transmissions. This highlights the situation where an early transmitter ($t_2$) may be unaware that a later transmitter ($t_3$) can increase its interference power in the course of its transmission, even though the later transmitter ($t_3$) ensures its locally measured aggregate interference power to be below $t_{cs}$.

Based on Example 2, the ordering effect always happens regardless of the value of power-sensing threshold $t_{cs}$. However, depending on the value of $t_{cs}$, such effect may or may not prevent interference-safe transmissions. This raises the question that how we can set a proper power-sensing threshold to ensure interference-safe transmissions despite of the ordering effect.

**III. MODEL AND NOTATIONS**

Before presenting the results for a proper power-sensing threshold to avoid the problems in Examples 1-2, we provide some formal definitions. Consider a dense network setting with a set of links $X$. For $i \in X$, we denote $t_i$ as the transmitter, and $r_i$ as the receiver. Note that a receiver may be associated with more than one transmitters, and some receiver may be also a transmitter in another link. We also write $t_i$ and $r_i$ as the respective coordinates. Let

$$\text{dist}(i, j) \triangleq \min(|t_j - r_i|, |r_j - t_i|, |r_j - r_i|, |t_j - t_i|)$$

which is the minimum distance among the transmitters and receivers between a pair of links $i, j$.

To capture the feasible states that are interference-safe in the presence of possible ACKs, we define the following feasible family of subsets of concurrently transmitting links.

**Definition 1:** (Bi-directional interference-safe feasible family $\mathcal{S}_{\text{ag}}^{\text{bi}}[X, \beta] \subseteq 2^X$): A subset of links $S$ are interference-safe ($S \in \mathcal{S}_{\text{ag}}^{\text{bi}}[X, \beta]$), if and only if for all $i \in S$,

$$P_{tx}|t_i - r_i|^{-\alpha} \geq N_0 + \sum_{j \in S \{i\}} P_{tx} \cdot \text{dist}(i, j)^{-\alpha} \geq \beta$$

$\mathcal{S}_{\text{ag}}^{\text{bi}}[X, \beta]$ generalizes the commonly used feasibility condition in SINR model for uni-directional communications. CSMA is supposed to enable the links in $X$ to operate within the constraint of $\mathcal{S}_{\text{ag}}^{\text{bi}}[X, \beta]$, requiring no coordination among the links, for instance by only local interference power measurement. That is, if the subsets of links allowed to transmit simultaneously by a carrier-sensing mechanism are always within the feasible family $\mathcal{S}_{\text{ag}}^{\text{bi}}[X, \beta]$, then the carrier sensing mechanism is said to be hidden-node free. To model APCS, a simple approach is to consider the following feasible family as in [6].

**Definition 2:** (Simple aggregate carrier-sensing feasible family $\mathcal{S}_{\text{ag}}^{\text{simp}}[X, t_{cs}] \subseteq 2^X$): A subset of links $S$ are permitted by carrier-sensing ($S \in \mathcal{S}_{\text{ag}}^{\text{simp}}[X, t_{cs}]$), if and only if for all $i \in S$,  

$$P_{tx}|t_i - r_i|^{-\alpha} \geq N_0 + \sum_{j \in S \{i\}} P_{tx} \cdot \text{dist}(i, j)^{-\alpha} \geq \beta$$

$\mathcal{S}_{\text{ag}}^{\text{simp}}[X, t_{cs}]$ generalizes the commonly used feasibility condition in SINR model for uni-directional communications. CSMA is supposed to enable the links in $X$ to operate within the constraint of $\mathcal{S}_{\text{ag}}^{\text{simp}}[X, t_{cs}]$, requiring no coordination among the links, for instance by only local interference power measurement. That is, if the subsets of links allowed to transmit simultaneously by a carrier-sensing mechanism are always within the feasible family $\mathcal{S}_{\text{ag}}^{\text{simp}}[X, t_{cs}]$, then the carrier sensing mechanism is said to be hidden-node free. To model APCS, a simple approach is to consider the following feasible family as in [6].
\[ N_0 + \sum_{j \in S} P_{tx}|t_j - t_i|^{-\alpha} \leq t_{cs} \tag{9} \]

"Aggregate" carrier-sensing refers to sensing the aggregate interference power in APCS, rather than the pairwise interference power as in IPCS. Hidden node problem can be resolved, if we can find a proper power-sensing threshold \( t_{cs} \) such that
\[
\mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \subseteq \mathbb{R}^{ag}_{N_0, P_{tx}}[X, \beta] \tag{10}\]

However, \( \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \) does not take into account the ordering of local measurements, which can cause underestimation of interference by the transmitters that started to transmit earlier. More accurately, a feasible state in CSMA with local interference power measurement is characterized by a sequence of transmitters, instead of a subset of concurrent links. Thus, we define a more appropriate notion of feasible family for APCS as follows.

\textbf{Definition 3:} (Aggregate carrier-sensing feasible family \( \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \)): We write \( S \) as a sequence \( (i_1, \ldots, i_S) \) and each \( i_k \in X \). A sequence of transmitters \( S \) is permitted by carrier-sensing \( (S \in \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}]) \), if and only if for all \( i_k \),
\[
N_0 + \sum_{j \in \{i_1, \ldots, i_{k-1}\}} P_{tx}|t_j - t_i|^{-\alpha} \leq t_{cs} \tag{11}\]

That is, when each transmitter \( i_k \) sees the interference power from other concurrent transmitters that have started transmissions before is below the power-sensing threshold \( t_{cs} \), \( i_k \) decides that it is allowed to transmit.

For brevity of presentation, we also denote a sequence \( S \) as the set of its ordered items. For example, if \( S = (i_1, i_2, i_3) \), we also denote \( S \) as a set, such that \( S = \{i_1, i_2, i_3\} \).

Our goal is to study how to set the power-sensing threshold \( t_{cs} \) to eliminate hidden node. Namely, we aim at finding a proper value of \( t_{cs} \), such that
\[
S \in \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \Rightarrow S \in \mathbb{R}^{ag}_{N_0, P_{tx}}[X, \beta] \tag{12}\]

We are interested in the maximal value of \( t_{cs} \) without the complete knowledge of \( X \). In the following, we suppose that we only know the maximum transmission distance \( r_{tx} \) \( \triangleq \max_{i \in X} |t_i - r_i| \) in a priori, when setting \( t_{cs} \). Alternatively, \( r_{tx} \) can be interpreted as the maximum tolerable transmission distance for a given \( t_{cs} \). Note that even without the knowledge of \( r_{tx} \), for fixed constants \( \alpha, \beta, N_0, P_{tx} \), the upper bound for transmission distance is \( |t_i - r_i| \leq (P_{tx})^{1/\alpha} \).

\section{IV. \textbf{Power-Sensing Threshold}}

This section presents a general approach to eliminate hidden nodes by local interference power measurement by setting a proper power-sensing threshold \( t_{cs} \).

To eliminate hidden node, we rely on the notion of interference level at transmitter \( t_i \) with respect to a subset of links \( S \), which is defined as:
\[
I_i[S, \alpha] \triangleq \sum_{j \in S} |t_j - t_i|^{-\alpha} \tag{13}\]

We denote the maximal interference level in Euclidean space \( \mathbb{R}^d \), subject to \( \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \) with background noise \( N_0 \), by:
\[
\Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[t_{cs}, \alpha] \triangleq \max_{X, S \in \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}]} I_i[S, \alpha] \tag{14}\]

\textbf{Lemma 1:} \( \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[t_{cs}, \alpha] \) has the following properties:
\[
\Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[t_{cs}, \alpha] = (t_{cs} - N_0) \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[N_0 + 1, \alpha] \tag{15}\]
\[
\Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[t_{cs}, \alpha] = \frac{1}{P_{tx}} \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[1, \alpha] \tag{16}\]

\textbf{Proof:} See the Appendix.

Let the normalized maximal interference level be
\[
\Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[\alpha] \triangleq \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[0, \alpha] = [1, \alpha] \tag{17}\]

Note that \( \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[\alpha] \) is a fundamental parameter depending on the the dimension of the space, and provides a key theoretical tool to determine a proper power-sensing threshold to ensure interference-safe transmissions.

\subsection{A. \textbf{Sufficient Condition}}

We next provide a sufficient condition. Define bi-directional interference level at link \( i \) w.r.t. a subset of links \( S \) as:
\[
B_i[S, \alpha] \triangleq \sum_{j \in S} \text{dist}(i, j)^{-\alpha} \tag{18}\]

We denote the maximal bi-directional interference level in Euclidean space \( \mathbb{R}^d \), subject to \( \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \) with background noise \( N_0 \), by:
\[
\Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[t_{cs}, \alpha] \triangleq \max_{X, S \in \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}]} B_i[S, \alpha] \tag{19}\]

\textbf{Lemma 2:} Let \( r_{tx} \triangleq \max_{i \in X} |t_i - r_i| \). If
\[
t_{cs} \leq P_{tx} \left( \frac{r_{tx}^{-\alpha}}{P_{tx}} \right) \left( \frac{1}{\beta} \right)^{1/\alpha} + N_0, \tag{20}\]

then
\[
\Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[t_{cs}, \alpha] \leq \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[t', \alpha] \tag{21}\]

\textbf{Proof:} See the Appendix.

\textbf{Theorem 1:} Given a set of links \( X \), which lies in Euclidean space \( \mathbb{R}^d \), let \( r_{tx} \triangleq \max_{i \in X} |t_i - r_i| \). If we let
\[
t_{cs} \leq P_{tx} \left( 2r_{tx} + \frac{1}{\Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[\alpha]} \right) \left( \frac{r_{tx}^{-\alpha}}{P_{tx}} \right) \left( \frac{1}{\beta} \right)^{1/\alpha} + N_0 \tag{22}\]

then it can eliminate hidden nodes in APCS,
\[
S \in \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \Rightarrow S \in \mathbb{R}^{ag}_{N_0, P_{tx}}[X, \beta] \tag{23}\]

\textbf{Proof:} Suppose that \( S \in \mathbb{C}_{N_0, P_{tx}}^{ag}[X, t_{cs}] \), and \( t'_{cs} \) satisfies Eqn. (20). Recall that \( \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[\alpha] = \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[1, \alpha] \). Then, by Lemmas 2 and 1, we obtain:
\[
\frac{P_{tx} t_{cs}^{-\alpha}}{N_0 + \sum_{j \in S_1(t)} P_{tx} \cdot \text{dist}(i, j)^{-\alpha}} \geq \frac{P_{tx} t_{cs}^{-\alpha}}{N_0 + P_{tx} \sum_{j \in S_1(t)} t'_{cs}^{-\alpha}} \geq \frac{P_{tx} t_{cs}^{-\alpha}}{N_0 + (t'_{cs} - N_0) \Gamma_{\text{max}, N_0, P_{tx}}^{ag,d}[\alpha]} \tag{24}\]
Because of the restriction of placement of nodes in \( R \) according to Algo. 1. Alternatively, as in Algo. 1, the obtained result is however critical to the more realistic uncertain parameters from the channel model. We observe that the thresholds are relatively robust against uncertainty parameters from the channel model.

In particular, when \( N_0 = 0 \), then

\[ t_{cs} \leq P_{tx} \left( \left( 2 + \left( \frac{1}{P_{max}[\alpha]} \right)^{\frac{1}{\alpha}} \right) r_{tx} \right)^{\alpha} \]

(27)

In the following, we derive \( I_{max}^{\alpha}[\alpha] \) for the 1-D and 2-D cases in the next sections.

V. POWER-SENSING THRESHOLD: 1-D CASE

Although the 1-D case \( R \) (the real line) seems too simple, the obtained result is however critical to the more realistic 2-D case in the next section. In order to use Theorem 1 to determine a proper power-sensing threshold, we consider the worst case topology that generates \( I_{max}^{\alpha}[\alpha] \). We consider a large set of points with coordinates labeled as \((t_0, t_1, t_2, \ldots, T)\). It can be shown that \( I_{max}^{\alpha}[\alpha] \) is obtained via solving the following optimization problem:

\[
(M) : \max \sum_{i=1}^{T} \left| t_i - t_0 \right|^\alpha \text{ subject to } \\
\sum_{j=1}^{k-1} \left| t_k - t_j \right|^\alpha \leq 1 \text{ for all } k = 1, \ldots, T
\]

Because of the restriction of placement of nodes in \( R \), we can also make use of a greedy placement algorithm to solve MaxI. The basic idea is to sequentially place the \( i \)-th node \( t_i \) in \( R \) such that the distance \( |t_i - t_0| \) is minimized subject to:

\[
I_{i, \{t_0, \ldots, t_{i-1}\}, \alpha} = \sum_{t_j = t_{i-1} + 1}^{t_i} \left| t_i - t_j \right|^\alpha = 1
\]

(28)

The interference level at \( t_0 \) w.r.t. an infinite sequence \( \{t_1, t_2, \ldots, \} \) is the maximal interference level \( I_{max}^{\alpha}[\alpha] \). In fact, greedy placement algorithm can be implemented by balanced placement around \( t_0 \), in the positive and negative real lines alternatively, as in Algo. 1.

We show the correctness of Algo. 1 by Lemma 3.

**Lemma 3:** \( I_T \) is the output of Algo. 1, \( \lim_{T \to \infty} I_T = I_{max}^{\alpha}[\alpha] \).

We defer the proof to the technical report [9].

---

**Algo. 1 Greedy1d:** Input (\( \alpha \), max step \( T \)), Output (\( I_T \))

1. Put \( t_0 \) at the origin of \( R \)
2. \( S_0 \leftarrow (t_0) \)
3. for \( i = 1, \ldots, T \) do
   4. if \( i \) is odd then
      5. Place \( t_i \) in \( R \) such that \( t_i > \max S_{i-1} \)
      6. else
      7. Place \( t_i \) in \( R \) such that \( t_i < \min S_{i-1} \)
   8. end if
   9. \( S_i \leftarrow (t_0, \ldots, t_{i-1}, t_i) \)
10. end for
11. return \( I_T = \sum_{t_j \in S_T \setminus \{t_0\} } \left| (t_0 - t_j) \right|^\alpha \)

---

**Fig. 3.** Nodes are placed in \( R \) according to Algo. 1.

We next evaluate \( I_T \) from Algo. 1. We let \( d_i \triangleq |t_{2i-1} - t_{2i-3}| \) and \( c_i \triangleq |t_{2i} - t_{2i+2}| \) (see Fig. 3). We obtain:

\[
I_T = \sum_{t_j \in S_T \setminus \{t_0\} } \left| (t_0 - t_j) \right|^\alpha
\]

(29)

One can solve \( \{c_i, d_i\}_{i=1,2,\ldots} \) from the above equations. Then the maximal interference level is obtained by

\[
I_{max}^{\alpha}[\alpha] = \sum_{n=1}^{\infty} (c_1 + \ldots + c_n)^{-\alpha} + \sum_{n=1}^{\infty} (d_1 + \ldots + d_n)^{-\alpha}
\]

(30)

Numerically, we evaluate \( \{c_i, d_i\}_{i=1,2,\ldots} \) for the case \( \alpha = 2 \), and estimate that \( I_{max}^{\alpha}[2] \approx 2.59 \).

However, it is difficult to obtain \( \{c_i, d_i\}_{i=1,2,\ldots} \) for general \( \alpha \). Next, we obtain an upper bound for \( I_{max}^{\alpha}[\alpha] \).

First, we note that

\[
d_1 < c_1 < d_2 < c_2 < \ldots < d_{k-1} < c_{k-1} < d_k < c_k < \ldots
\]

(31)

It is because that the locally measured interference level w.r.t. \( S_{i-1} \) at each \( t_i \) is 1 in Algo. 1, and hence \( t_i \) should have an increasing distance to the closest node in \( S_{i-1} \).

Hence, we obtain:

\[
c_1 + d_1 < c_1 + c_1 \implies (c_1 + d_1)^{-\alpha} > (c_1 + c_1)^{-\alpha} \implies 1 \leq \frac{(1 + 2^{-\alpha})}{(1 + 2^{-\alpha})}
\]

(32)
Similarly, we obtain:
\[
1 = (d_k)^{-\alpha} + (d_{k-1} + d_k)^{-\alpha} + \ldots + (d_1 + \ldots + d_k)^{-\alpha}
  + (c_1 + d_1 + \ldots + d_k)^{-\alpha} + \ldots
  + (c_{k-1} + \ldots + c_1 + d_1 + \ldots + d_k)^{-\alpha}
\]
\[
> (d_k)^{-\alpha}(1 + 2^{-\alpha} + \ldots + (2k-1)^{-\alpha})
\]
\[
\Rightarrow \quad d_k > \left( \sum_{i=1}^{2k-1} i^{-\alpha} \right)^{1/\alpha} \tag{34}
\]
\[
1 = (c_k)^{-\alpha} + (c_k + c_{k-1})^{-\alpha} + \ldots + (c_k + \ldots + c_1)^{-\alpha}
  + (c_k + \ldots + c_1 + d_1 + \ldots + d_k)^{-\alpha} + \ldots
  + (c_k + \ldots + c_1 + d_1 + \ldots + d_k)^{-\alpha}
\]
\[
\Rightarrow \quad c_k > \left( \sum_{i=1}^{2k} i^{-\alpha} \right)^{1/\alpha} \tag{36}
\]

Thus, we obtain an upper bound \( \bar{I}_1[\alpha] > I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{max}} \) as follows:
\[
\begin{align*}
I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{max}}[\alpha] &= \sum_{n=1}^{\infty} (c_1 + \ldots + c_n)^{-\alpha} + \sum_{n=1}^{\infty} (d_1 + \ldots + d_n)^{-\alpha} \\
&< \bar{I}_1[\alpha] \triangleq \sum_{n=1}^{\infty} \left( \sum_{k=1}^{n} \left( \sum_{i=1}^{2k-1} i^{-\alpha} \right)^{1/\alpha} \right)^{-\alpha} \\
&\quad + \sum_{n=1}^{\infty} \left( \sum_{k=1}^{n} \left( \sum_{i=1}^{2k-1} i^{-\alpha} \right)^{1/\alpha} \right)^{-\alpha} \tag{37}
\end{align*}
\]

Numerically, we evaluate \( \bar{I}_1[\alpha] \) in Fig. 4 by summing only the first \( n \) terms in the outmost summation of \( \bar{I}_1[\alpha] \). We observe that \( \bar{I}_1[\alpha] \) converges quickly (see Fig. 4).

![Fig. 4. Numerical values of \( \bar{I}_1[\alpha] \) of the first \( n \) terms in the summation.](image)

We tabulate the values of \( \bar{I}_1[\alpha] \) via numerical study in Table V.

<table>
<thead>
<tr>
<th>( \alpha )</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>

</table>

Note that \( I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{max}}[2] \approx 2.59 \) by numerical study. Hence, the upper bound appears to be tight.

VI. POWER-SENSING THRESHOLD: 2-D CASE

Obtaining the maximal interference level \( I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{max}}[\alpha] \) for Theorem 1 in the 2-D case is more complicated, because there are many more possible locations for nodes in Euclidean space \( \mathbb{R}^2 \). By numerical solving (MaxI) for the case of \( \alpha = 3 \) with a large \( T \), we obtain \( I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{max}}[3] \approx 4.2 \).

We next give a upper bound for \( I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{ag,2}}[\alpha] \). Recall the sequence of separation distances \( (d_1, d_2, \ldots) \) from the definition in Fig. 3 for the 1-D case. We set the spacing distance in the hexagonal grid to be \( d_1 = 1 \).

Nodes are placed as hexagonal rings around \( t_0 \) (see Fig. 6). We denote the set of nodes in hexagonal grid for the \( i \)-th ring by \( H_i = \{ t_1^i, \ldots, t_n^i \} \). Particularly, \( t_1^i \) are placed on the positive horizontal real line in \( \mathbb{R}^2 \). We set the separation distance between the rings according to sequence \( (d_1, d_2, \ldots) \). Namely, the location of \( t_1^i \) in \( \mathbb{R}^2 \) is \( ([\sum_{j=1}^{i} d_j], 0) \).

![Fig. 5. Nodes are placed evenly around \( t_0 \) in hexagonal grid.](image)

![Fig. 6. Nodes are placed as hexagonal rings, separated by \( d_i \).](image)

We can upper bound \( I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{ag,2}}[\alpha] \) from Fig. 6. For each \( i \)-th ring, \( |H_i| = 6(\sum_{j=1}^{i} d_j) \). By Eqn. (34), we obtain:
\[
\begin{align*}
I_{\alpha, \alpha, \alpha, \alpha, \alpha, \alpha}^{\text{ag,2}}[\alpha] &< \bar{I}_1[\alpha, \alpha, \alpha, \alpha, \alpha, \alpha] \\
&< \sum_{n=1}^{\infty} 6(d_1 + \ldots + d_n)^{-\alpha+1} \tag{38}
\end{align*}
\]

Numerically, we evaluate \( \bar{I}_2[\alpha] \) in Fig. 7 by summing only the first \( n \) terms in the outmost summation of \( \bar{I}_2[\alpha] \). We observe that \( \bar{I}_1[\alpha] \) converges quickly as \( n \) increases. We tabulate the values of \( \bar{I}_2[\alpha] \) via numerical study in Table VI.

![Fig. 7. Numerical values of \( \bar{I}_2[\alpha] \) of the first \( n \) terms in the summation.](image)

VII. COMPARISON TO IPCS

Besides of APCS, an alternate approach is to use the pairwise interference power as in IPCS [7]. The basic idea of Incremental-Power Carrier-Sensing (IPCS) is that \( t_i \) can
estimate the distance to each individual concurrent transmitter \( t_k \) by measuring the change of interference power. Suppose that initially \( t_i \) measures the aggregate interference power as: 
\[
P_{t_i}[\mathcal{N} \setminus \{t_k\}] = P_{\text{tx}}|t_k - t_i|^{-\alpha},
\]
(39)
which reveals the distance \(|t_k - t_i|\). Suppose that each transmitter \( t_i \) maintains a counter \( \text{cnt}_i \) (initially set as 0). When \( t_i \) detects any change \( \Delta P_i \),
- if \( \Delta P_i \geq P_{\text{tx}}r_{cs}^{-\alpha} \), then \( \text{cnt}_i \leftarrow \text{cnt}_i + 1 \).
- if \( \Delta P_i \leq -P_{\text{tx}}r_{cs}^{-\alpha} \), then \( \text{cnt}_i \leftarrow \text{cnt}_i - 1 \).
Transmitter \( t_i \) is allowed to transmit only if \( \text{cnt}_i = 0 \).

In idealized CSMA protocol, congestion avoidance countdown is based on a continuous random variable. Hence, it is likely that no transmitters will simultaneously start to transmit at the same time. In such a setting, IPCS realizes a pairwise carrier-sensing feasible family as follows:

**Definition 4:** (Pairwise carrier-sensing feasible family \( \mathcal{C}_{N_0,P_{\text{cs}}}^\text{pw}[X,r_{cs}] \subseteq 2^X \)) A subset of links are permitted by pairwise carrier-sensing \( S \in \mathcal{C}_{N_0,P_{\text{cs}}}^\text{pw}[X,r_{cs}] \), if and only if for all \( i,j \in S \),
\[
|t_j - t_i| \geq r_{cs}
\]
(40)
We denote the maximal interference level in Euclidean space \( \mathbb{R}^d \), subject to \( \mathcal{C}_{N_0,P_{\text{cs}}}^\text{pw}[X,r_{cs}] \) with background noise \( N_0 \), by:
\[
I_{\text{max},d}^\text{pw}[r_{cs},\alpha] \triangleq \max_{X \in \mathcal{C}_{N_0,P_{\text{cs}}}^\text{pw}[X,r_{cs}], i \in S} I_t[S,\alpha]
\]
(41)
A natural question is which mechanism among APICS and IPCS is better. One may compare the size of feasible families between aggregate carrier-sensing and pairwise carrier-sensing. Nonetheless, we note that the feasible family of aggregate carrier-sensing \( \mathcal{C}_{N_0,P_{\text{ag}}}^\text{ag}[X,t_{cs}] \) is a collection of sequences of transmitters, whereas that of pairwise carrier-sensing \( \mathcal{C}_{N_0,P_{\text{cs}}}^\text{pw}[X,t_{cs}] \) is a collection of subsets of links.

To have a fair comparison, we set \( t_{cs} \) and \( r_{cs} \), such that \( I_{\text{max},d}^\text{pw}[r_{cs},\alpha] = I_{\text{max},d}^\text{ag}[t_{cs},\alpha] \). Namely, the maximum interference level at a transmitter by APICS or IPCS is the same.

In such a setting, we show in [9] that there exists a set of links \( X \), such that there is a feasible sequence in \( \mathcal{C}_{N_0,P_{\text{ag}}}^\text{ag}[X,t_{cs}] \), but there is no corresponding feasible set of its ordered members in \( \mathcal{C}_{N_0,P_{\text{cs}}}^\text{pw}[X,t_{cs}] \). Also, we show in [9] that there exists a set of links \( X \), such that there is a feasible set in \( \mathcal{C}_{N_0,P_{\text{cs}}}^\text{pw}[X,t_{cs}] \), but not all sequences of its members are in \( \mathcal{C}_{N_0,P_{\text{ag}}}^\text{ag}[X,t_{cs}] \). Hence, neither approach is superior to one another in terms of feasibility.

**VIII. PERFORMANCE EVALUATION**

We perform simulations to evaluate the relative performance of APICS as compared to IPCS. We also consider a “benchmark” approach, as proposed by [7]. This is essentially APICS, but the power-sensing threshold \( t_{cs} \) is set as:
\[
t_{cs} \leq P_{\text{tx}}(r_{cs})^{-\alpha} + N_0
\]
(42)
where \( r_{cs} \) is the carrier-sensing range for IPCS obtained from [7]. Namely, we set \( t_{cs} \) to implement IPCS by APICS.

In our simulations, the nodes are placed in a square area of 300m x 300m. The locations of the transmitters are generated according to a Poisson point process and clustered Poisson point process. The length of a link is uniformly distributed between 10 and 20 meters. The receiver associated with a transmitter is randomly located between the two concentric circles of radii 10m and 20m centered on the transmitter. We study the performance under different values of countdown window (CWin) in the CSMA protocol.

We consider \( \alpha = 3 \), and use \( I_{\text{max,pw}}^\text{ag}[t_{cs}] \approx 4.2 \). We compare the average throughput among the links and fairness measured by Jain index, \( JI = \frac{\sum_{i=1}^{n} S_i}{n \cdot \sum_{i=1}^{n} S_i^\alpha} \), where \( S_i \) is throughput of link \( i \) in the total \( n \) links. The large value of \( JI \) means more fair.

1. (Known channel parameter): For \( \alpha = 3 \), we plot the results in Fig. 8. We observe that APICS has similar average throughput as IPCS, and significantly outperforms IPCS under clustered point model. The fairness of APICS is more biased under Poisson point model, but is same as IPCS under clustered point model. In all cases, APICS outperforms the benchmark approach. It is because APICS depends on only the aggregate interference, rather the pairwise interference in the neighborhood, APICS is more suitable for clustered environment than IPCS, where links are clustered together.

2. (Uncertain channel parameter): When \( \alpha \) is a independently random variable in the range [2, 4] for each pair of links, we plot the results in Fig. 9. We observe that APICS has a better average throughput than IPCS, and the fairness is similar under Poisson point model and clustered point model. This is due to the fact that APICS measures the sum of interference from all links, and is less vulnerable to the random fluctuation of pathloss exponent \( \alpha \) from an individual link as in IPCS. This suggests that APICS is a more robust solution in the presence of uncertain pathloss exponent from the channel model.

**IX. CONCLUSION**

Interactions between links in realistic CSMA networks are affected by the special properties attributed to SINR, effects of arbitrary ordering of local measurements, and ACK frames. Without proper consideration of these properties, interference among simultaneous links can cause considerable performance degradation to CSMA networks. This paper presents the first viable standard-compatible solution to ensure interference-safe transmissions by determining a proper interference-safe power-sensing threshold in Aggregate-interference-Power Carrier-Sensing (APICS). We remark that our solution does not require modification to the existing CSMA protocol.

X. APPENDIX: PROOFS

A. Proof of Lemma 1

Proof: To prove Eqn. (15), suppose \( \bar{X} \) and \( \bar{S} \) gives the maximal interference level for \( I_{\text{max},N_0,P_{\text{tx}}}[N_0+1, \alpha] \). Since \( \bar{X} \) lies in \( \mathbb{R}^d \), we can multiply the distances between all transmitters in \( \bar{X} \) by a factor of \( (t_{\text{cs}} - N_0)^{-1/\alpha} \). We denote such a set of rescaled transmitters as \( \bar{X}' \). Namely,

\[
|t_{i}' - t_{j}'| = (t_{\text{cs}} - N_0)^{-1/\alpha}|t_{i} - t_{j}|
\]

(43)

where \( t_{i}', t_{j}' \in \bar{X}' \), \( t_{i}, t_{j} \in \bar{X} \). It is easy to see that

\[
N_0 + \sum_{i \in \{i_1, \ldots, i_{k-1}\}} P_{\text{tx}}|t_{i} - t_{k}|^{-\alpha} \leq N_0 + 1
\]

\[
\Rightarrow N_0 + \sum_{i \in \{i_1, \ldots, i_{k-1}\}} P_{\text{tx}}|t_{i} - t_{k}|^{-\alpha} \leq t_{\text{cs}}
\]

(44)

where \( (i_1, \ldots, i_k) = \bar{S} \) and \( (i_1', \ldots, i_k') = \bar{S}' \), and \( \bar{S}' \) is the induced sequence of \( \bar{S} \) in the rescaled \( \bar{X}' \).

Hence, the induced \( \bar{S}' \) must also give the maximal interference level for \( I_{\text{max},N_0,P_{\text{tx}}}[t_{\text{cs}}, \alpha] \). Therefore,

\[
I_{\text{ag},N_0,P_{\text{tx}}}[t_{\text{cs}}, \alpha] = \sum_{S \subseteq \bar{S}'} |t_{i}' - t_{j}'|^{-\alpha} = (t_{\text{cs}} - N_0) \sum_{j \in \bar{S}} |t_{j} - t_{i}|^{-\alpha}
\]

\[
= (t_{\text{cs}} - N_0) I_{\text{max},N_0,P_{\text{tx}}}[N_0 + 1, \alpha]
\]

(45)

To prove Eqn. (16), it follows a similar approach. However, we multiply the distances between all transmitters in \( \bar{X}' \) by a factor of \( P_{\text{tx}}^{-1/\alpha} \).

B. Proof of Lemma 2

Proof: Suppose \( S = (i_1, \ldots, i_S) \in \mathcal{C}_{N_0,P_{\text{tx}}}[X, t_{\text{cs}}] \). By Eqn. (11), for any pair \( i_j, i_k \in S \) and \( j < k \), we obtain:

\[
N_0 + \sum_{i \in \{i_1, \ldots, i_{k-1}\}} P_{\text{tx}}|t_{i} - t_{k}|^{-\alpha} \leq t_{\text{cs}}
\]

\[
\Rightarrow |t_{i} - t_{k}| \geq \left( \frac{t_{\text{cs}} - N_0}{P_{\text{tx}}} \right)^{-\alpha} \geq \left( \frac{t_{\text{cs}} - N_0}{P_{\text{tx}}} \right)^{-\alpha} + 2r_{\text{tx}}
\]

(46)

Since \( |t_{i} - r_{i}| \leq r_{\text{tx}} \) and \( |t_{k} - r_{k}| \leq r_{\text{tx}} \), by triangular inequality,

\[
|t_{i} - r_{k}| \geq |t_{i} - t_{k}| - |t_{k} - r_{k}| \geq \left( \frac{t_{\text{cs}} - N_0}{P_{\text{tx}}} \right)^{-\alpha} + r_{\text{tx}}
\]

(47)

\[
|t_{i} - r_{k}| \geq |t_{i} - t_{k}| - |t_{k} - r_{k}| \geq \left( \frac{t_{\text{cs}} - N_0}{P_{\text{tx}}} \right)^{-\alpha} + r_{\text{tx}}
\]

(48)

\[
|t_{i} - r_{k}| \geq |t_{i} - t_{k}| - |t_{k} - r_{k}| \geq \left( \frac{t_{\text{cs}} - N_0}{P_{\text{tx}}} \right)^{-\alpha} + r_{\text{tx}}
\]

(49)

\[
|t_{i} - r_{k}| \geq |t_{i} - t_{k}| - |t_{k} - r_{k}| \geq \left( \frac{t_{\text{cs}} - N_0}{P_{\text{tx}}} \right)^{-\alpha} + r_{\text{tx}}
\]

(50)

Hence,

\[
dist(i, j) \geq \left( \frac{t_{\text{cs}} - N_0}{P_{\text{tx}}} \right)^{-\alpha}
\]

(51)

\[
\Rightarrow N_0 + \sum_{i \in \{i_1, \ldots, i_{k-1}\}} P_{\text{tx}} \cdot dist(i, j) \cdot t_{\text{cs}}^{-\alpha} \leq t_{\text{cs}}
\]

(52)

We define a new feasible family \( \mathcal{C}_{N_0,P_{\text{tx}}}[X, t_{\text{cs}}] \), such that \( S \in \mathcal{C}_{N_0,P_{\text{tx}}}[X, t_{\text{cs}}] \), if and only if Eqn. (52) holds for all \( i_k \in S \). It follows that

\[
S \in \mathcal{C}_{N_0,P_{\text{tx}}}[X, t_{\text{cs}}] \Rightarrow S \in \mathcal{C}_{N_0,P_{\text{tx}}}[X, t_{\text{cs}}]
\]

(53)

Hence,

\[
B_{\text{ag},N_0,P_{\text{tx}}}[t_{\text{cs}}, \alpha] \leq \max_{X,S \in \mathcal{C}_{N_0,P_{\text{tx}}}[X, t_{\text{cs}}], i \in S} B_{1}[S, \alpha]
\]

(54)

We complete the proof by:

\[
\max_{X,S \in \mathcal{C}_{N_0,P_{\text{tx}}}[X, t_{\text{cs}}], i \in S} B_{1}[S, \alpha] \leq B_{\text{ag},N_0,P_{\text{tx}}}[t_{\text{cs}}, \alpha]
\]

(55)
